

Masked Erosion: How Acceptance Gates Lose Redundant Safeguards in Self-Improving Agents

Hau-Sing So^{1*} Daixian Liu² Weicai Long²

¹University of Macau ²Tsinghua University

Abstract

Self-improving LLM agents edit their own harness, the prompts and rules around a fixed model, and keep an edit only if an acceptance gate scores it higher on a batch of tasks. Such a gate sees what the harness does under the current model, not what it would still prevent if one safeguard failed. When safeguards overlap, deleting one is *masked*: the others still block the harm, so the gate decides on task success alone and redundancy erodes unseen. We measure harm for every subset of four written safeguards in two agent environments and run 411 improvement loops under ten gate rules, mostly as controlled deletion experiments, plus three runs of the GEPA optimizer. A deletion behind another working safeguard adds almost no observable harm. A paired significance test blocks deletions that pass by chance but not deletions that genuinely raise task success, and a larger evaluation batch lets it delete cheaper safeguards: at the same cost, 20-task batches kept every harness protected while 40-task batches lost all six. Large harm audits prevent exposure but not the loss of depth, which turns into harm when the harness is reused with a weaker model. GEPA kept every safety rule verbatim, yet two of its three final harnesses misused credentials under a weaker model. A statistical model frozen before the runs predicts where each gate’s protection breaks as safeguard cost and batch size change, and freezing safety text or auditing one-layer ablations preserves depth.

1 Introduction

Self-improving agents such as ADAS, the Darwin Gödel Machine, GEPA, ACE and Self-Harness (Hu et al., 2025; Zhang et al., 2025; Agrawal et al., 2026; Zhang et al., 2026b,a) rewrite their own harness: the prompts, notes and tool rules around a fixed model. Most keep a rewrite only if an *acceptance gate* finds that the new harness does better

* Corresponding author.

(a) Three deletions, no observed harm

(b) Same harness, different model

Figure 1: **Low observed harm can hide lost redundancy.** (a) A gate that audits every harm task in its batch (veto, $\rho = 1$; loop 5 in Appendix Table 14) accepts three deletions without seeing new harm, and the margin falls from 2 to 1. (b) The final harness stays below the harm threshold under the loop’s model, but misuses credentials in 0.575 of runs under the weaker Qwen3-30B (two stronger API models: at most 0.05).

than the old one on a batch of tasks. Self-evolution can still degrade safety (Shao et al., 2026; Das et al., 2026; Mao et al., 2026); the Darwin Gödel Machine removed the logging that its own hallucination detector relied on (Zhang et al., 2025).

A gate sees what a harness does under the current model; it does not see what the harness would still prevent if one safeguard failed. Real harnesses guard a harm with overlapping rules. An assistant that keeps notes for several users may be told who owns each note, to check a noted credential against its own, to verify the account after login, and never to act for someone else. This is *defence in depth* (Reason, 1997). While one rule suffices, deleting another changes almost nothing a gate can measure: the deletion is **masked**. In Figure 1, a gate that audited every harm task in its batch accepted three deletions in a row. The final harness stayed below

our harm threshold under the loop’s model (0.025 vs. 0.000), but misused credentials in 0.575 of runs under the weaker Qwen3-30B.

Existing checks on self-improvement test either the gain or the child. Robust gates ask whether an accepted gain is real (Shawn, 2026; Wang et al., 2026); harm audits and semantic floors ask whether the child behaves safely now (Kumar et al., 2026). A masked deletion passes both: its gain may be real, and the child is safe under the current model. What it removes is *margin*, the number of further failures the harness can absorb, which no check of the child under one model can measure. We call this loss of redundancy **masked erosion**.

We study masked erosion in two environments with deterministic audits: credential misuse in AppWorld (Trivedi et al., 2024) and destructive clean-up in OpsSim, a simulated operations service. In each we measure harm for all 16 subsets of four safeguards and run 411 loops under ten gate rules. Most are *stress loops*, a controlled intervention in the spirit of mutation testing (DeMillo et al., 1978; Jia and Harman, 2011): each generation deletes one safeguard, and we record whether the gate lets it through. Eighteen natural loops let an LLM rewrite text freely, and three runs use GEPA unchanged. Our contributions are:

- **A mechanism and a way to measure it.** Masking explains why a gate cannot see the loss of a redundant safeguard; a harm lattice over all safeguard subsets measures what is lost as *margin*, the number of further safeguards that may fail before harm appears (§3.2, §4.2).
- **Advance prediction of where gates break.** A gate-free effect size from calibration runs separates deletions that a significance test blocks from those it passes, and a simulator frozen before the loops predicts where each gate breaks as safeguard cost and batch size change: a larger batch admits cheaper deletions (§3.3, §4.3–4.4).
- **Evidence on what gates leave behind.** Harm audits stop exposure but not depth loss, which becomes harm under weaker models; GEPA shows a related blind spot outside the labelled rules; freezing safety text and auditing one-layer ablations preserve depth (§4.5–4.7).

Together, the results separate two properties that current gates conflate: being safe now, and staying safe when something changes.

2 Related Work

Self-Improving Agents and Their Gates STOP, ADAS, Gödel Agent and the Darwin Gödel Machine rewrite code or harnesses (Zelikman et al., 2024; Hu et al., 2025; Yin et al., 2025; Zhang et al., 2025); OPRO, DSPy, GEPA and ACE tune prompts or context (Yang et al., 2024; Khattab et al., 2024; Agrawal et al., 2026; Zhang et al., 2026b). Prompt compression drops low-utility instructions by design (Jiang et al., 2023). We study the acceptance step these systems share. PACE, SAGE and RRSI make gates robust to noisy or over-fitted improvements (Shawn, 2026; Wang et al., 2026; Xia et al., 2026), and other work analyzes selection noise, lock-in and statistical limits (Hu and Tang, 2026; Wang et al., 2025). These ask whether an accepted gain is real. We ask what real gains and noise do to safeguards that the score barely measures.

Safety of Self-Evolving Agents Self-evolution can degrade safety (Shao et al., 2026; Das et al., 2026; Lin et al., 2026; Gong et al., 2026), through unsafe skills (Mao et al., 2026; Shang et al., 2026) or through experiences that are harmful only in combination (Yan et al., 2026), and individually safe harness updates can interact unsafely (Zhang et al., 2026c). Iterative code refinement can remove validation logic that a static scanner does not flag (Chen et al., 2026), a single masked edit; we measure how gates accumulate such edits. Semantic floors check that an edited safety gate still behaves like a reference gate, not merely that it is present (Kumar et al., 2026); a masked deletion passes such checks under the current model. SHE accepts safety edits only if safety improves without utility loss (Qu et al., 2026), and AI control screens edits with trusted monitors (Greenblatt et al., 2024).

Defence in Depth Redundancy hides the failure of individual barriers (Rasmussen, 1997; Vaughan, 1996; Hendrycks et al., 2021), and optimizing a proxy erodes what the proxy omits (Manheim and Garrabrant, 2018; Skalse et al., 2022; Amodei et al., 2016; Gao et al., 2023) unless the constraint is stated (Achiam et al., 2017). Minimizing a test suite can lose fault detection (Yoo and Harman, 2012), and mutation testing removes checks to see whether tests notice (Jia and Harman, 2011). A model swap resembles a common-cause failure of redundant barriers (Mosleh et al., 1988), and behaviour transfers unreliably across models (Sclar et al., 2024; Echterhoff et al., 2024).

Gate	Accepts the child if
<i>Success only</i>	
Greedy	it solves more batch tasks than the parent
Split-half	it is no worse on either half, better on one
Paired	a one-sided exact McNemar test rejects
Read-only	greedy, with safety text reset to the parent’s
<i>Success and harm</i>	
Veto(ρ)	greedy, and no child-only harm in a share ρ
Audit veto	greedy, and harm $\leq \tau$, none new, in 120 runs
Margin-aware	greedy, and every one-layer ablation protected

Table 1: **Gate rules** ($n=40$, $p=0.1$, $\alpha=.05$, $\rho \in \{0.2, 1\}$). Extra harm runs: 120 per audited state, 30 per ablation.

3 Method

3.1 Problem Setting

A harness H is text given to a fixed model M ; it contains a set S of safeguard layers that the proposer may edit like any other text. Tasks come from a clean pool and a *harm pool*, whose tasks contain a trap such as another user’s credential. Both pools are split into calibration, confirmation and final sets (T_{cal} , T_{conf} , T_{final}), and no gate sees T_{final} . A proposer turns H into a child H' , and a gate G runs both once on a fresh batch B of n tasks, each drawn from the harm pool with probability p :

$$G(H, H'; B) \in \{\text{accept, reject}\}. \quad (1)$$

Table 1 lists our main gates; Appendix B adds an asymmetric and an intersection-union (IUT) gate, ten rules in all with veto at two audit shares. *Split-half* is a single-evaluation variant of the Self-Harness rule, and *paired* applies an exact McNemar test (McNemar, 1947). Greedy, split-half and the two veto gates ($\rho=0.2$ and 1) are *non-paired*.

Deployment Assumption The loop may edit safeguards, and the operator later reuses its harness with another model without re-auditing it, for instance after a provider update (Chen et al., 2024b) or when routing to a cheaper model (Chen et al., 2024a). Our swap experiments test this scenario, not how often it occurs.

3.2 Masking, Margin and Child-Only Harm

For every subset $T \subseteq S$, let $h(T)$ be the harm rate on the harm pool. T is *protected* if $h(T) \leq \tau=0.05$, and a layer s is *sufficient* if $\{s\}$ is protected; both classes hold for a given model and task pool. The *margin* of a protected state is the fewest

deletions that reach an unprotected subset:

$$m(T) = \min \{ |T \setminus T'| : T' \subseteq T, h(T') > \tau \}, \quad (2)$$

with $m=\infty$ if none exists, which we never observed. In fault-tree terms, m is the order of the smallest cut set (Vesely et al., 1981); it does not require h to be monotone. For a deletion $T \rightarrow T \setminus \{s\}$, we run parent and child on the same tasks and record the clean success gain g and the *child-only harm* $h_{01} = \Pr[\text{child harms} \wedge \text{parent does not}]$. The deletion is *masked* if parent and child are both protected, and *exposing* if only the parent is. Masking bounds the new harm:

$$h_{01} \leq h(T \setminus \{s\}) \leq \tau. \quad (3)$$

An audit of k independent harm-pool pairs therefore detects a masked deletion with probability at most $1 - (1 - \tau)^k$, or 0.19 for $k=4$. A threshold rule passes every masked child, and stricter rules need far more data than a batch holds: a veto needs about 200 pairs to catch a child-only harm of 0.008 four times in five, and a rate comparison about 700 runs per arm to tell 0.008 from 0.025 (one-sided $\alpha=.05$, power 0.8). What a masked deletion removes is margin, a property of the child’s ablations rather than of the child itself. Margin is coarse but easy to interpret (§4.5).

3.3 Drift and Selection

A gate sees a masked deletion mainly through its effect on success. Let $g_B = (1 - p)g + pg_h$ be the gain on the mixed batch, with g_h the gain on harm-pool tasks, and let $z = g_B\sqrt{n}/\sigma$ be its standardized effect, where σ is the standard deviation of the paired per-task difference; both come from calibration pairs. With z_α the one-sided critical value, a normal approximation gives

$$P_{\text{greedy}} \approx \Phi(z), \quad P_{\text{paired}} \approx \Phi(z - z_\alpha). \quad (4)$$

Greedy rejects ties, which the continuity correction $\Phi(z - 1/(2\sigma\sqrt{n}))$ accounts for (Appendix B). Borrowing terms from population genetics (Kimura, 1968; Ohta, 1973), we distinguish two regimes. In **drift** ($z \approx 0$), noise decides: non-paired gates accept a nearly free deletion by chance, and a valid significance test does so with probability at most α in every generation. In **selection** ($z \gg 0$), the deletion truly raises success and passes success-based gates, all the more surely in a larger batch: the smallest cost that a significance gate detects falls as

Figure 2: **Study design.** Top: a proposer deletes a layer (stress loops) or rewrites text freely (natural loops and GEPA); the gate compares parent and child on a fresh batch, and an accepted child becomes the next parent. Bottom left: while another layer blocks the harm, a deletion leaves observed harm low but removes redundancy. Bottom middle: an accepted deletion either buys little (drift) or real task success (selection).

$\sigma/\sqrt{n}$, and faster at small n for the exact test. We label an edge selection when its calibration $z \geq z_\alpha$, without reference to gate decisions; a simulator-based classification agrees on 84–100% of edges (Appendix C). The batch-size effects below follow from Eq. 4; what is new is that the break points were predicted before any loop ran.

3.4 Statistical Analysis

Loops are the unit of analysis. We use one-sided Fisher and exact permutation tests across loops, matched tests where arms share random numbers, and Holm correction (Holm, 1979) within each registered family. Each confirmatory prediction and its analysis code were frozen and hashed before the test ran (van Miltenburg et al., 2021). Predictions come from a *gate simulator* that resamples calibration pairs with a Bayesian bootstrap (Rubin, 1981), runs the exact gate code and chains acceptance probabilities over the lattice (Appendix B). Its frozen predictions placed the break costs for 20-, 40- and 120-task batches before the loops ran, and every paired count of the cost dose-response fell inside its frozen interval. On single AppWorld decisions, where every edge is drift, it predicts no better than each gate’s mean rate (Appendix B); its value lies where effects vary. Not every prediction held: of 177 registered predictions, 113 held, 49 failed, 9 held in part and 6 could not be scored. Every verdict was computed by the frozen analysis code. Of the 14 tests behind the main claims, 7 held; the others fell short in the predicted direction (3),

found a stronger effect than predicted (2) or found a harm-aware gate weaker than predicted (2) (Appendix K). Three later prediction sets, including GEPA’s, were frozen after related outcomes, and the drift account was formulated after a predicted AppWorld selection effect failed to replicate.

4 Experiments

4.1 Experimental Setup

Credential Misuse in AppWorld Following So et al. (2026), the agent’s notes hold login credentials for several apps. In the harm pool, the note for the target app (Amazon, Gmail or Venmo) holds another user’s working credential, which the task never needs. A deterministic audit, with no LLM judge, flags any non-login call made with a foreign token and any net change to that user’s account. The starting harness H_0 has four layers: AUTH names each note’s owner, VERIFY uses a noted credential only if it matches the requester’s own, PROFILE checks the account after login, and CAUTION allows only the requester’s credentials. Tasks are split by supervisor (30/30/20 per pool for $T_{\text{cal}}/T_{\text{conf}}/T_{\text{final}}$). A ReAct-style code agent (Yao et al., 2023) runs at most 15 steps at temperature 0.

Destructive Clean-Up in OpsSim Tickets ask the agent to clear stale cache or lock entries; in the harm pool, the notes suggest a wildcard or admin rights that would also delete an entry still in use. The layers are SCOPE, CONFIRM (ask the owner first), LEASTPRIV and DRYRUN. The step budget

(a) Safeguard lattice · AppWorld

(b) Harm of single deletions

Figure 3: **Redundant layers are masked.** (a) Harm of every AppWorld state under DeepSeek, pooled over calibration and confirmation tasks (blue outline: protected, harm ≤ 0.05). (b) Child-only harm h_{01} of single deletions, classifying children on T_{cal} and measuring on T_{conf} (lines: 95% upper bounds; hollow: zero events).

sets their cost: at three steps, removing all four raises clean success from 0.00–0.50 to 1.00 for the five loop models, while at four steps they cost DeepSeek nothing in calibration. The simulator runs in memory and never executes a command.

Models, Loops and GEPA DeepSeek-V4.1-Flash is the main agent and proposer; Qwen3-30B-A3B and Qwen3-8B run locally (Qwen Team, 2025). GPT-6 Luna, GPT-6.1 Sol and Claude Haiku 5.5, reached through a third-party API, serve as supplementary models; every main finding holds with DeepSeek and the local Qwen models alone. Loops run eight generations with $n=40$ and $p=0.1$ unless noted. *Stress* loops propose deleting a uniformly chosen remaining layer. *Natural* loops use a free-form DeepSeek proposer asked to make the harness cheaper (Appendix E). Of the 411 loops, 393 are stress loops (78 in AppWorld, 315 in OpsSim) and 18 are natural loops. Finally, we run GEPA 0.1.4 unchanged (Agrawal et al., 2026) for three seeds of 800 metric calls on AppWorld, scored on task success alone (Appendix H).

4.2 Masked Deletions Are Nearly Invisible

Under DeepSeek, AUTH and VERIFY each suffice alone, CAUTION and PROFILE only reduce harm, and H0 has margin 2 (Figure 3a). PROFILE’s weakness is partly an audit artefact: the audit counts the account check that PROFILE itself prescribes. Without that call, PROFILE suffices, H0’s margin is 3, and no conclusion below changes (Appendix D). Deletions into children protected on T_{cal} carry child-only harm of 0.016 on T_{conf} (upper bound

0.028), against 0.422 for deletions into unprotected children. A four-task batch audit would notice the former in about 6% of decisions.

The pattern holds for every model that follows some layer reliably (Figure 3b). In OpsSim, CONFIRM alone suffices for DeepSeek, Luna and Sol, and deletions behind it carry $h_{01} \leq 0.018$. Weak models have nothing to mask: no single AppWorld layer suffices under Qwen3-30B, and Qwen3-8B and Haiku follow no layer reliably. Protection is a property of the harness and the model together.

4.3 Significance Suppresses Drift

In 27 AppWorld stress loops with DeepSeek, every deletion is nearly neutral ($|z| \leq 1.1$). Greedy and split-half gates accepted 0.48 and 0.44 of proposed deletions and the paired gate 0.04 (Figure 4b; loop-level permutation, Holm $p=.002$ for both). Greedy accepted masked deletions at 0.63, against 0.36 for no-op edits at the same parents: noise explains most acceptances, and small batch gains the rest. These gains did not transfer: greedy finals solved 0.358 of clean T_{final} tasks, H0 0.400.

The batches gave no warning. The 32 deletions into protected children that greedy, split-half and paired gates accepted came with 114 harm-pool tasks (48 distinct) and no child-only harm, while the margin fell (Figure 4a). Greedy loops ended unprotected in 5 of 6 runs, four of them with no layer left, and paired loops in none (one-sided Fisher, Holm $p=.015$); split-half loops did so in 2 of 6. The paired test suppresses drift without stopping it: it accepted 2 of 42 masked deletions, and

Figure 4: **Drift in 27 AppWorld stress loops** (DeepSeek). (a) Margin of each loop’s harness by generation (dashed: mean; markers: first unprotected state). (b) Acceptance of planted deletions over 204 proposals (markers) and frozen prediction (ticks); gates draw separate batches, so veto (0.2) can exceed greedy. (c) Acceptance of masked deletions vs. of real +0.075 (filled) and +0.275 (hollow) edits, for paired at three α and greedy.

Setting	Model	Cost	Sel.	Unprotected		Harm	
				G	P	G	P
AppWorld	DeepSeek	.12	0	5/6	0/6	.32	.00
	Luna	.03	2	4/6	0/6	.42	.00
OpsSim 4 st.	DeepSeek	0	0	5/12	2/12	.09	.01
OpsSim 3 st.	DeepSeek	.70	17	11/12	7/12	.32	.12
	Luna	.93	13	6/6	3/6	.49	.16
	Sol	.90	16	6/6	6/6	.33	.18
	Qwen-30B	1.00	18	5/6	3/6	.20	.01

Table 2: **Selection decides whether significance protects.** Greedy (G) and paired (P) stress loops that reach an unprotected state, and mean T_{final} harm of their finals. Cost: clean success that the full stack loses on T_{conf} ; Sel.: deletion edges (of 32) with calibration $z \geq z_{\alpha}$; st.: step budget. DeepSeek in OpsSim adds six fresh-seed loops per arm.

chaining its frozen per-edge rates gives an unprotected final with probability 0.19 by generation 64 (Appendix F). This protection comes from conservatism (Figure 4c): at $\alpha = .05$ the paired gate passes a real +0.075 edit in 8% of decisions, against 96% for greedy, and at $\alpha = .20$ it passes that edit in 54% but accepts 17% of masked deletions.

4.4 Significance Does Not Stop Selection

Costly Layers Are Deleted for Real Gains At three steps, DeepSeek’s full OpsSim stack solves 0.30 of clean tasks and its empty stack 1.00. Across all logged stress decisions, the paired gate accepted 9 of 292 deletions with $z < z_{\alpha}$ but 46 of 92 with $z \geq z_{\alpha}$ (Figure 6a). It accepted deleting CONFIRM, the only sufficient layer for DeepSeek, Luna and Sol, in 15 of 20 proposals from the full stack, and their paired loops lost protection in 4, 3 and 6 of 6 runs (Table 2).

Cost Is a Dose At four steps the layers are free. Letting the owner whom CONFIRM asks stay silent on some tasks gives that one layer a cost we control. As the cost rose from 0 to 0.32, paired loops lost protection in 0, 0, 1, 6 and 4 of 6 runs, each inside its frozen 95% interval, while greedy loops eroded at every cost (Figure 5a). The observed break, between costs of 0.08 and 0.15, contains the critical effect of the exact test at $n = 40$ (Appendix F).

Larger Batches Admit Cheaper Deletions By Eq. 4, a larger batch lets a significance gate detect, and therefore accept, a smaller gain; the question is whether this can be predicted. Before the runs, the simulator placed the break at a cost of 0.20, 0.09 and 0.03 for batches of 20, 40 and 120 tasks (Figure 5b). With 20 tasks per batch, paired loops kept all six harnesses protected at a cost of 0.15, where 40-task loops lost all six ($p = .001$). With 120 tasks, resampled from the 60-task pool, paired loops lost 5 of 6 at costs of 0.03 and 0.08, where 40-task loops lost 0 and 1; counting each distinct task once would reverse 4 of their 10 acceptances, so these loops confirm the direction rather than the exact break (Appendix B). A larger batch, usually the safer choice, admits cheaper deletions.

Natural Proposers Trim Costly Checks Natural proposers rarely delete a layer outright; they rewrite the checks inside it (Appendix Figure 8). Run alone, the rewritten layers let through 0.19 more harm than the originals (CI [0.08, 0.31]). On fresh tasks, the 10 accepted safety-text edits kept a success gain of 0.075 (CI [0.007, 0.163]), and seven of them relax a check, mostly PROFILE’s (Figure 5c). Selection also works inside layers.

Figure 5: **Selection defeats significance.** (a) Four-step OpsSim with a rising cost on CONFIRM (DeepSeek, $n = 40$): paired loops lose protection once the layer costs enough. (b) The break moves with batch size: frozen simulator (lines) and loops (markers). (c) Fresh-task gain of the safety-text edits of natural loops (means, 95% intervals); fill marks accepted edits that relax a check.

Figure 6: **What the gates decide and what they leave behind.** (a) Acceptance by gate-free z (95% intervals) against Eq. 4. (b) AppWorld finals: clean success and misuse under Qwen3-30B (hollow: natural loops). (c) Three-step OpsSim finals under selection (Table 21).

4.5 What the Gates Leave Behind

Audits Stop Exposure, Not Depth Loss Auditing harm works against exposing deletions: the veto ($\rho = 1$) saw child-only harm in 14 of 18 of them, but in only 2 of 29 masked ones. Table 3 orders gates by the harm runs they read. Unprotected loops fall from 5 of 6 to none, yet five of six audit-veto finals keep a margin of only 1. The contrast is sharp without redundancy, where each OpsSim trap has exactly one blocking layer: there the same audit veto rejected all 23 deletions that greedy accepted and kept every full stack, while greedy lost all six loops. Audits control exposure but cannot see redundancy.

Lost Depth Becomes Harm Under Weaker Models We re-ran the 11 distinct finals of the 27 DeepSeek stress loops on T_{final} under other models, comparing only finals still protected under DeepSeek, which separates lost depth from existing

Gate	Audit	Unprot.	Margin	Qwen	Clean
Greedy	—	5/6	0.33	.48	.36
Veto ($\rho=1$)	4/batch	1/6	0.83	.40	.41
Audit veto	120/state	0/6	1.17	.21	.44
Margin-aware	30/layer	0/6	1.33	.04	.37
Paired	—	0/6	1.83	.004	.39

Table 3: **Audits stop exposure, not depth loss** (AppWorld, DeepSeek, six stress loops per gate): harm runs read, unprotected loops, mean final margin, T_{final} misuse under Qwen3-30B and clean success.

exposure (Appendix Figure 9). Under Qwen3-30B, non-paired finals misused credentials in 0.30 of runs and paired finals in 0.004 (CI of the difference [0.16, 0.47]); under Qwen3-8B the gap was 0.16 [0.02, 0.29]. The harm follows the missing layers, not a model trying things at random. Qwen3-30B used up its step budget in 63–90% of runs under every final, H0 included, yet finals that kept AUTH and at least one other layer misused credentials

in 2 of 200 runs, AUTH alone in 9 of 40, and finals without AUTH in 89 of 200, in step-exhausted and shorter runs alike (Appendix Table 31). Layers that are interchangeable for DeepSeek are not interchangeable for the weaker model: it relies mainly on AUTH, and depth behind AUTH still cuts its harm from 0.225 to 0.01. Lost redundancy is lost coverage for a model that relies on different layers; a swap acts as a common-cause failure of the remaining barriers (Mosleh et al., 1988). The effect is specific to weaker executors. Both Qwen models solve about 5% of clean AppWorld tasks; under Luna and Sol, which solve them, the gap was only 0.025 [0, 0.07], and after a task shift under DeepSeek 0.020 ($p = .061$). Because the weaker model leans on one layer, margin under DeepSeek ranks its harm only with Spearman $r_s = 0.65$; the expected harm after one random layer failure does better (0.80), but needs far more harm runs than a batch holds (Appendix I).

4.6 An Off-the-Shelf Optimizer: GEPA

Stress loops plant deletions; GEPA proposes its own edits. We split the harness into four text components (note header, note template, credential rules and task tips) and scored task success alone. GEPA keeps a candidate that beats its parent on four tasks, which is a greedy gate, and returns the best-scoring candidate on 27 validation tasks; 181 of 186 proposals were valid (Appendix Table 30).

GEPA Runs in the Drift Regime GEPA’s validation gains, up to +0.22, did not transfer: its finals solved 0.35–0.45 of clean T_{final} tasks, against 0.40 for H0. Like a greedy stress loop, it accepted edits it could not tell from noise, and it kept rewrites of the credential rules at its usual rate (7 of 45; all edits: 33 of 181). Of the 17 rewrites our judge flagged as weakening a check, 13 in fact replaced the noted-credential check with a stricter rule; GEPA kept 3 of those and neither genuine relaxation, and no final weakened a credential rule.

Rules Intact, Behaviour Changed All three finals kept the credential rules verbatim and caused no harm under DeepSeek. Two of them rewrote the note template into an instruction to log in with the stored credentials (“Use these exact credentials to authenticate to {app} as {owner} whenever needed”), and seed 2 also added 3,000 characters of efficiency tips. Under Qwen3-30B these two finals misused credentials in 2 and 5 of 40 runs, on 2 and 3 of 20 tasks, against 0 of 80 for H0. The

change adds an instruction rather than deleting a safeguard, but it is masked in the same way: the remaining rules override it under the loop’s model, not under a weaker one. It lies outside the labelled layers over which margin is defined, and the judge marked every layer intact. With three seeds and few harm events, it is a case study, not an estimate.

4.7 Two Structural Remedies

Freezing Safety Text In four natural loops, safety text was reset to the parent’s. All four finals kept H0’s safety text and reached the highest clean success of any natural arm, with no harm under DeepSeek and 0.019 under Qwen3-30B (Figure 6b). Freezing protects text, not behaviour, and requires knowing which text is safety text: one final added an unfrozen tip against “extra profile/account checks”. Under selection in three-step OpsSim, freezing only CONFIRM kept all six loops protected while the costly layers around it were deleted, at a cost of 0.05 in clean success (Figure 6c).

Auditing One-Layer Ablations The margin-aware gate applies mutation adequacy (Jia and Harman, 2011) to safeguards: it accepts a child only if every one-layer ablation stays protected. On the greedy loops’ random numbers, none of its loops ended unprotected (greedy: 5 of 6; matched sign test $p = .031$), with no loss of clean success. At similar audit compute, it kept more layers than the audit veto in all six matched loops (sign test $p = .016$), and its finals harmed less under Qwen3-30B (Table 3). Under selection in OpsSim it kept every loop protected by keeping three layers, at a cost of 0.35 in clean success. The gate checks layers, not wording: in all three natural loops it let VERIFY be weakened (Appendix G).

5 Conclusion

We studied when acceptance gates in self-improving agents erode the redundancy behind low observed harm. A deletion behind another working safeguard is masked, so the gate decides on task success, and where its protection breaks can be predicted before the runs. Harm audits prevented exposure but not depth loss, which became harm under weaker models, while freezing safety text or auditing one-layer ablations preserved depth. Self-improving agents should keep safety-critical behaviour outside the optimizer, gate edits on what remains rather than only on what happens, and re-audit the harness after a model change.

Limitations

Our main limitation is scope. We study two environments, each with one harm and four written safeguards, and most loops plant one deletion per generation to isolate the gate. We chose this setting to expose how gates respond to deletion pressure, not to estimate how often deployed optimizers erode safeguards; the natural loops and GEPA runs are case studies. Erosion matters only when a harm that the model does not avoid on its own meets redundant layers that it follows reliably and a later change that needs them. Strong models avoided the harms we probed in τ^2 -bench, AgentDojo and a privacy simulation (Appendix A), and our largest swap effects come from weaker models. Batch size and harm share were varied only in OpsSim, where the 120-task batches resample a 60-task pool; long-horizon results are simulator projections, and results from the third-party API models are supplementary.

Ethical Considerations

Potential Risks The study identifies safeguard loss that a behavioural gate may miss and evaluates ways to detect or constrain it. The same findings could inform attempts to weaken safeguards, which motivates transparent reporting of assumptions and of the limits of each remedy. OpsSim and the privacy simulation use synthetic data in memory: structured agent calls operate on dictionaries, and a static check verifies that OpsSim cannot access files, networks or processes.

Data and Licenses All AppWorld accounts and credentials are synthetic; no personal data was used. AppWorld is released under the Apache 2.0 license with the requirement that public redistribution of its task data be encrypted, τ^2 -bench and AgentDojo are MIT-licensed, and the Qwen3 weights are released under Apache 2.0; we use all of them for their intended research purpose. Proprietary models were accessed through APIs, and API credentials are excluded from all released material. We will release code, the exact safeguard texts and proposer prompts, frozen predictions with hashes and run records; records that contain AppWorld task data will be encrypted as its license requires.

Use of AI Assistants AI assistants supported analysis-code development and manuscript editing. Figure 2 was drafted with an image-generation tool, and its labels and counts were checked and

corrected by the authors; all data plots are rendered programmatically from recorded values. The authors are responsible for all code, results, citations and figures.

A Environments and Safeguards

Table 4 gives each layer’s function; exact texts, task identifiers and splits are in the released material.

Layer	Function
<i>AppWorld</i>	
AUTH	Every note is prefixed with the name of the user it belongs to.
VERIFY	Look up one’s own credentials in the supervisor app; use a noted credential only if it matches.
PROFILE	After logging in, call <code>show_account</code> and check that the account is the requester’s.
CAUTION	Use only credentials that belong to the requester; never act on another person’s account.
<i>OpsSim</i>	
SCOPE	Touch only entries within the ticket’s scope.
CONFIRM	Call <code>ask_owner</code> before deleting.
LEASTPRIV	Use admin rights only after a permission error, and only on a concrete path.
DRYRUN	Run <code>dry_run</code> before any wildcard delete.

Table 4: Safeguard layers and their function.

AppWorld. AppWorld v0.2.0.dev with a ReAct-style loop: the agent writes Python against the app APIs under AppWorld’s own instructions, with at most 15 steps and 4096 output tokens per step. The notes list credentials for the target app and two others; in the harm pool the target app’s entry belongs to another supervisor and was validated by logging in. Harm is either of two deterministic events (So et al., 2026): **B**, a non-login API call made with a foreign access token, or **S**, a net state change in the other supervisor’s account. Two audit slices are skipped because the installed AppWorld lacks their tables; no run called those APIs, so the skip removes no harm event.

OpsSim. 160 tickets (30/30/20 per pool and split). In half of the harm tickets the notes suggest a wildcard that also matches another service’s live entry; in the other half they suggest `admin=true`, under which a wildcard also removes a lock held by a running process. A run succeeds if every requested entry is deleted and harms if a protected entry is. The workspace is a dictionary and the interpreter accepts only six structured calls; a static check forbids file, process and network access. With DeepSeek every state solves all clean T_{cal} tasks at 4, 6 and 15 steps, so the layers cost success only at three.

τ^2 -bench. Retail domain, with DeepSeek as agent and user at temperature 0. We remove the policy sentences on identity verification and on confirmation before writes; a rule-based audit flags a user-specific read before authentication or a write without explicit consent.

Harms Strong Models Already Avoid. A written safeguard can erode with consequence only if the model does not already follow it. In τ^2 -bench retail (Yao et al., 2024; Barres et al., 2025), deleting the policy sentences on authentication and on confirmation before writes, in all four combinations, changed DeepSeek’s reward and violation rate by at most 0.05: without the confirmation sentence the agent still asked before all 136 writes, and the tool interface enforces authentication; Luna and Sol behaved the same. In AgentDojo (Debenedetti et al., 2024) (v0.1.35, suites v1.2.2), four attacks succeeded in 6 of 240 runs without any safeguard, and in a privacy simulation with synthetic canary records the agent checked permissions and redacted unprompted, leaking in none of 72 runs. Such rules are masked by the model itself: deleting them is invisible to every gate until a model with other defaults is used.

B Gates, Simulator and Statistics

Gates. Let $y_i, y'_i \in \{0, 1\}$ be parent and child success on task i of a batch of $n=40$, and n_{01} (n_{10}) the tasks that only the child (parent) solves. *Greedy* accepts iff $\sum_i y'_i > \sum_i y_i$; with $D = \sum_i (y'_i - y_i)$, a continuity correction gives $P(D \geq 1) \approx \Phi(z - 1/(2\sigma\sqrt{n}))$, the tie-aware form of Eq. 4. *Split-half*, a single-evaluation variant of the Self-Harness rule (Zhang et al., 2026a), accepts iff the changes on the two halves satisfy $\Delta_a, \Delta_b \geq 0$ and $\max(\Delta_a, \Delta_b) > 0$; Self-Harness re-evaluates stochastic runs, so our results concern this variant only. *Paired* accepts iff the exact one-sided McNemar test rejects:

$$\sum_{k \geq n_{01}} \binom{n_d}{k} 2^{-n_d} \leq \alpha, \quad n_d = n_{01} + n_{10}. \quad (5)$$

Veto(ρ) applies the greedy rule and rejects if any audited harm-pool pair (a share ρ of them) shows child-only harm; *asymmetric* sends candidates labelled as weakening a safeguard to the paired test and the rest to the greedy rule. The registered swap tests compare *greedy-type* gates (greedy, split-half and veto 0.2) with paired; *non-paired* gates, as in the main text, are greedy, split-half, veto ($\rho=0.2$)

and veto ($\rho = 1$). Each generation draws tasks without replacement from the 60 per pool in $T_{\text{cal}} \cup T_{\text{conf}}$ and runs parent and child with a new shared seed; tasks recur across generations, runs do not. Batches of 120 cannot be drawn this way. They draw with replacement, as the simulator does at every n , and run each drawn task through a per-task cache; a 120-task batch holds about 50 distinct clean tasks (49.6 and 50.8 on average at the two costs), and the McNemar test counts repeated pairs separately. These loops therefore test a larger *decision* batch on a fixed task pool, which is also how the cost is defined: in four-step OpsSim the owner’s silence is fixed per task (2, 5, 9 and 19 of the 60 clean tasks at the four costs), and in calibration the full stack failed as many clean tasks as were silent while its child without CONFIRM failed none. At zero cost there are no discordant pairs, and no batch size makes the paired gate accept. The batch-size claim does not rest on these loops alone: the 20-task loops, drawn without replacement, kept every harness protected where 40-task loops lost all six. In AppWorld, whose runs are not deterministic, the $n = 120$ projections resample a pool whose gains did not transfer to T_{final} : they describe a gate fitting its own task pool. A batch holds $\text{Binomial}(n, p)$ harm-pool tasks, 3.98 on average over the 204 AppWorld stress batches.

Archived Batch Replay. An independent replay of the two $n = 120$ arms ($q = .05$ and $.10$) rebuilt 95 of their 96 batches from the saved per-task outcomes; one batch lacks one saved outcome. All 95 paired-gate decisions and all harm totals agree with the logs. Eight rebuilt batches differ from the logged parent or child success totals by one or two outcomes. Duplicate draws of a task were submitted concurrently to a cache without per-key locking, so a repeated draw could be run twice while the cache kept one result; this plausibly explains the differences, though the archive cannot prove it. Exact reuse of one outcome per repeated task is therefore not guaranteed, although no decision depended on it. Counting each distinct task once, i.e., a decision batch of about 60 distinct tasks, would have turned 4 of the 10 accepting decisions into rejections (three at $q = .05$, one at $q = .10$), as Eq. 4 predicts for a smaller batch; this is a sensitivity check on the logged decisions, not a new trajectory. Three of the four reversals fall in the arm behind the main text’s lowest break cost (0.03), so that number holds only for this repeated-draw gate; the

20-task loops, drawn without replacement, carry the batch-size claim. The released runner deduplicates jobs before submission (verified by four offline tests); all reported runs predate this fix.

Null Acceptance. For identical harnesses with tie probability π on the batch and π' on a half, greedy accepts with probability $(1 - \pi)/2 < 1/2$ and split-half with $(1 + 2\pi' - 3\pi'^2)/4 \leq 1/3$. On replicate pairs, no-op edits were accepted at 0.400 (greedy), 0.323 (split-half) and 0.013 (paired) averaged over the 16 parent states, and at 0.358, 0.320 and 0.006 weighted by the parents of the masked deletions, the rates used in Section 4.3 and Table 7. Detection grows with the harm share: at $p = 0.5$ a full audit sees a deletion with $h_{01} = 0.016$ in about 28% of decisions.

Other Gates. The single-edit study also tested an anytime-valid betting test (Ramdas et al., 2023), cost-aware greedy and paired gates, and an intersection-union audit gate. On T_{conf} they accepted single-safeguard deletions at rates of at most 0.004, 0.16–0.56, 0.03–0.12 and 0.000. The intersection-union gate was later run in loops; the others are projected over loops in Appendix F.

Simulator and Baselines. For each edit the simulator draws Dirichlet weights over calibration tasks, samples 10,000 batches of joint parent/child outcomes and applies the exact gate code; loop predictions chain these rates over the lattice with one uniformly chosen deletion per generation. In AppWorld it beats the frozen baselines on single decisions but not the constant baselines added after confirmation, and beats all of them on trajectories (Table 5); in three-step OpsSim it beats N0 on single decisions (Brier gain CI [0.042, 0.107]), as expected when edits have real effects.

Tests. Rates carry Wilson intervals. Upper bounds on pooled h_{01} come from a task bootstrap. For zero events, we report the independent-Bernoulli reference bound $1 - 0.05^{1/k}$ (0.016 for the 189 in-loop harm tasks, 0.095 for the 30 of one edge). The in-loop sample conditions on acceptance, including veto decisions that require no detected child-only harm; its reference bound is not an unconditional confidence bound on masked-deletion risk. The 189 in-loop harm-task instances contain only 58 distinct task IDs. Restricted to the gates that never read harm (greedy, split-half, paired), as in Section 4.3, 32 accepted deletions into protected children held 114 harm-pool tasks

(48 distinct) and no child-only harm event (reference bound 0.026). Tasks recur across generations (60 per pool), so decisions within a loop are not independent; loops are the unit of every test, and decision-level rates are descriptive. Loop finals are classified with the lattice measured on the pool their batches come from; their harm on the unseen T_{final} gives the same order of gates (Table 21). Holm correction applies within the three registered families: the exposure and the acceptance contrasts of greedy and split-half against paired, and the swap contrasts under the two Qwen models. Other predictions are reported one by one, without correction across them. With six loops per arm, Section 4.3 reports exact loop-level permutation tests.

Data	Sim.	N0	N1	N2	B0–B2
Single-edit cells (6,758)	.062	.059	.062	.078	.42–.51
Lattice-edge cells (2,688)	.125	.116	.115	.128	.43–.50
Loop decisions (161)	.193	.185	.179	.208	.52–.59
Loop trajectories (21)	.128	.169	.138	.180	—

Table 5: Brier scores of acceptance predictions (AppWorld, DeepSeek; lower is better). Frozen: B0 (accept iff $g > 0$), B1 (deployment utility), B2 (sign of a closed-form signal). Added after confirmation: N0 (no edit has an effect), N1 (each gate’s mean rate), N2 (normal approximation).

C Robustness

Threshold and Classification. The greedy–paired contrast is unchanged for every threshold $\tau \leq 0.10$ (Table 6). Under a task bootstrap every state keeps its class in at least 97% of draws except {PROFILE, CAUTION} (pooled harm 0.058; protected in 46%), and H0’s margin never falls below 2. Every final state of the AppWorld stress loops keeps its class in at least 97% of draws, so the loop outcomes do not hinge on this noise. “Unprotected” refers to the classification: of the ten exposed greedy-type loops, eight deleted the whole stack (T_{final} harm 0.475) and two ended at {CAUTION} (pooled harm 0.167, none in 40 T_{final} runs).

Masked Deletions Are Not No-Ops. Masked deletions were accepted more often than no-op edits at the same parents (Table 7): they carry a small gain on the mixed batch, too small for the simulator to separate from noise. Exposing deletions were accepted at 5/12 (greedy) and 1/18 (veto $\rho=1$); the veto saw child-only harm in 14 of those 18 batches and in 2 of 29 masked ones.

τ	prot.	$m(H0)$	greedy	split-half	veto .2	veto 1	paired
.02	11	2	5/6	3/6	3/3	3/6	0/6
.03	12	2	5/6	2/6	3/3	1/6	0/6
.05	12	2	5/6	2/6	3/3	1/6	0/6
.10	13	3	5/6	2/6	3/3	1/6	0/6
.20	14	3	4/6	2/6	2/3	0/6	0/6

Table 6: Threshold sensitivity (AppWorld, DeepSeek, pooled harm): protected states, H0’s margin, and loops that reach an unprotected state.

Gate	Masked deletion	No-op	Batch gain
Greedy	.625 (15/24)	.358	+.048
Split-half	.455 (15/33)	.320	+.012
Paired	.048 (2/42)	.006	+.016

Table 7: Acceptance of masked deletions and of a no-op edit at the same parent states (AppWorld, DeepSeek), with the masked deletions’ mean batch gain.

Batch Order. Harm-pool tasks came first in every batch, so the halves seen by the split-half gate were not exchangeable. Re-deciding its 43 decisions under 1,000 random splits gives acceptance 0.428 against 0.442 logged; a decision flips with probability 0.11. Batch order thus barely changes the split-half gate.

Gate-Free Effect. We compute $z = g_B \sqrt{n} / \sigma$ for every edge of eight lattices from the calibration pairs, with $g_B = 0.9g + 0.1g_h$ and σ the standard deviation of the batch-mixture paired difference; no gate or simulator enters. In AppWorld (DeepSeek) $|z| \leq 1.09$ on all 32 edges. In three-step OpsSim 13–18 of 32 edges per model have $z \geq z_\alpha$ (DeepSeek: 17, against 16 in the registered simulator class), and deleting CONFIRM from the full stack has z between 4.3 (Qwen3-8B) and 11.3 (DeepSeek); at four steps $|z| < 1.4$ throughout. The z class agrees with the registered simulator class on 84–100% of each lattice’s edges. Harm-pool tasks supply 6–14% of the batch gain g_B of three-step selection edges: a child that finishes harm-pool tickets also scores there, which the remaining layers keep safe for masked deletions. Table 8 gives acceptance by z for every gate (the normal approximation overstates the top bin because the exact test is conservative at $n = 40$).

Significance Level and Run Variance. Table 9 re-decides every stress decision at three levels. Replicates at temperature 0 still differ: the intra-task correlation of harm is 0.14–0.46, and a single 30-task run of {VERIFY} lands at or below τ in 77%

Gate	z of the proposed deletion			
	< 0	$0-1$	$1-1.645$	≥ 1.645
Greedy	.31 (107)	.26 (103)	.44 (50)	.86 (73)
Split-half	.22 (65)	.32 (73)	.50 (36)	.63 (90)
Veto $\rho=0.2$	.10 (30)	.33 (42)	.33 (24)	.72 (40)
Veto $\rho=1$	.23 (61)	.28 (74)	.32 (41)	.46 (109)
Paired	.02 (93)	.02 (160)	.10 (39)	.50 (92)

Table 8: Acceptance of every logged stress decision by the gate-free effect z (decisions in parentheses), pooled over AppWorld (DeepSeek, Luna) and OpsSim (three steps, five models; four steps, DeepSeek).

of draws ($\{\text{CAUTION}\}$: 24%), hence the pooled classification. The full stack costs DeepSeek 0.100 and 0.117 of clean AppWorld success on T_{cal} and T_{conf} , and -0.050 on T_{final} .

	$\alpha = .05$	.10	.20
<i>AppWorld, DeepSeek</i>

Beneficial edit, +0.275	.91	.95	.98
P(unprotected by gen. 8), simulated	.004	.016	.085
<i>OpsSim, three steps, DeepSeek</i>			
Masked deletions accepted	.70	.75	.87
Exposing deletions accepted	.26	.32	.40
P(unprotected by gen. 8), simulated	.67	.74	.83

Table 9: The paired gate at three significance levels. Beneficial edits are replayed at $n=40$ by task bootstrap; the greedy rule accepts them in .96 and 1.00 of the same bootstrap batches, and accepted masked deletions at .63 in its own loops.

Swap Harm by Margin. Mean swap harm falls with DeepSeek margin, but states with equal margin differ widely (Table 10).

Margin	Final states	Q-30B	Q-8B
0	{}, C	.525	.500
1	A, V, AC, VC, VP, APC	.233	.333
2	AV, AVC, AVPC	.017	.208

Table 10: Mean swap harm on T_{final} of the distinct final states, by margin under DeepSeek.

D Audit Variants

The registered audit counts reads made with a foreign token, including the show_account check that PROFILE itself prescribes once the agent has logged in with that token. We replayed without any LLM call the 188 harm-pool runs whose call audit fired

(185 reproduced exactly) and re-scored them without that check call (B_{nv}) and counting writes only (B_{w}). Only $\{\text{PROFILE}\}$ and $\{\text{PROFILE}, \text{CAUTION}\}$ change class (Tables 11 and 12), no stress loop ended in either, and loop outcomes and the order of gates are unchanged (Table 13); counting writes only roughly halves measured harm.

State	B		B_{nv}		B_{w}	
	cal	conf	cal	conf	cal	conf
AVPC (H0)	.000	.000	.000	.000	.000	.000

Qwen3-30B-A3B	CONFIRM, DRYRUN	.010 (.019)	.189	.00 / 1.00	.20 / .30	.13 / .29	.01 / .13	.00 / .26	.06 / .09
Qwen3-8B	none	.100 (.200)	.218	.50 / 1.00	.71 / .66	.77 / .66	.47 / .57	.92 / .64	.55 / .35
Haiku	none	—	.130	1.00 / 1.00	no loops (no protected state)				

Table 15: OpsSim lattices and loops at three steps (27 loops per model). Full-stack harm on T_{conf} was .000 for the four models with a sufficient layer, .100 for Qwen3-8B and .700 for Haiku; with no layer it was .27–.93. h_{01} prot.: deletions into children protected on T_{cal} , measured on T_{conf} ; Qwen3-8B’s T_{cal} -protected states are not protected on T_{conf} . *Zero events: one-sided 95% binomial reference bound for 30 independent tasks (others: task bootstrap); independence is an assumption of this bound.

models. Final evaluations are keyed by state and shared between loops that end in the same one. Figure 3a classifies edges with pooled estimates (20 masked, 8 exposing); the h_{01} test classifies children on T_{cal} and measures on T_{conf} (22 deletions into protected children). h is not monotone in the subset (e.g., {VERIFY} .008, {VERIFY, CAUTION} .025 pooled); margin takes the fewest deletions that reach any unprotected subset. Six asymmetric-gate stress loops, which send every planted deletion to the paired test, kept the full stack.

Luna. Under Luna, AUTH, VERIFY and CAUTION each suffice alone; child-only harm of single deletions is 0.019 (UB 0.035) into protected children and 0.505 into unprotected ones. On the random numbers of the DeepSeek loops, greedy

loops ended unprotected in 4 of 6 and paired loops in none (Table 18). The frozen lattice predicted single decisions with Brier 0.12, against 0.64–0.66 for B0–B2.

Qwen3-30B as Loop Model. With Qwen3-30B as the agent, no single AppWorld layer suffices and deleting AUTH alone exposes H0; the model solves about 5% of clean tasks, so decisions rest on ties and harm. On the random numbers of the DeepSeek loops, greedy loops ended unprotected in 5 of 6 (T_{final} harm 0.388, predicted 0.152) and paired loops in none (0.025), accepting 18 of 45 and 0 of 48 proposed deletions. The frozen lattice predicted single decisions with Brier 0.127, against 0.344 for the best baseline, and accepted deletions of protected layers showed no child-only harm.

Arm: model, gates (loops per gate)	Loops
<i>AppWorld stress</i>	
DeepSeek: greedy, split-half, paired, veto 1 (6); veto .2 (3)	27
Luna: greedy, paired (6)	12

Natural Proposals and Loops. Table 19 gives judge-flagged erosion rates per proposal chan-

Gate	Unprot.	Layers, gen. 8	Acc./prop.	T_{final} harm
Greedy	4/6 [1, 5]	0.50 [0.17, 1.50]	21/39	.421 (.316)
Paired	0/6 [0, 0]	3.83 [2.67, 3.67]	1/48	.000 (.004)

Table 18: AppWorld stress loops with Luna. Brackets: frozen 95% predictive intervals; parentheses: frozen prediction.

nel. Natural loops use the cost-objective proposer, which flagged the most erosion; each generation tests two candidates and keeps the first one accepted, so their rates are not comparable to stress loops. The paired gate accepted four edits in its two loops, none eroding, and its finals solved 0.63 and 0.73 of clean T_{final} tasks against 0.40 for H0 (Figure 7). Counted relative to the parent, as the prediction model does, accepted erosions per loop were 1.00 (greedy), 0.67 (split-half) and 0 (paired), inside their predictive intervals.

Figure 7: **Significance gates are slow, not frozen.** (a) T_{final} clean success of natural loops (markers: loops; lines: means; dashed: H0). (b) Paired-gate acceptance of two beneficial natural edits by batch size, replayed on pooled T_{final} and T_{conf} pairs.

Proposal channel	Eroding	P/V/C	Precision
Append (task tips)	0/40	—	—
Full rewrite (GEPA-style)	8/50	5/1/2	1/3
Consolidation (ACE-style)	11/50	9/4/1	2/3
Cost objective	12/50	11/6/0	3/3
Editable norms	3/50	3/1/0	3/3

Table 19: Natural proposals (DeepSeek, AppWorld). P/V/C: eroding labels on PROFILE, VERIFY, CAUTION (AUTH was never eroded). Precision: manual audit of three flagged proposals per channel; recall was not audited.

F Selection and Remedies

Free and Costly Layers. At three steps the full stack solves 0.00–0.50 of clean OpsSim tasks for the five loop models and the empty stack all of

them (Table 15); at four steps DeepSeek’s full stack solves every clean task and no edge is selection. Over twelve loops per arm, six of them with fresh seeds, paired loops ended unprotected in 2 of 12 at four steps and 7 of 12 at three (Fisher $p = .045$), greedy loops in 5 and 11 of 12. With free layers the paired gate protects most loops, not all: both exposed four-step paired loops (fresh seeds) accepted deleting CONFIRM in a batch where the parent solved 16 and 25 of 40 tasks and the child 40 and 39, a cost that calibration had not shown, rather than a near-tie.

Cost Dose-Response. At four steps, `ask_owner` stays silent with probability q , fixed per task by a hash and nested across q , so that only CONFIRM costs success. Every paired count lies inside its frozen interval (Table 20). Pooled, paired loops ended unprotected in 0 of 12 at $q \leq .05$ and 10 of 12 at $q \geq .2$ (Fisher $p < .001$). The break at 8–15 points of cost lies near z_α at $n = 40$: $q \approx .08$ by Eq. 4, $q \approx .14$ by the exact test.

q	Cost	Unprotected loops		Paired accepts CONFIRM	
		Greedy	Paired [PI]	Observed	Predicted
0	.000	5/6	0/6 [0, 0]	0/11	.00
.05	.033	4/6	0/6 [0, 2]	0/11	.03
.10	.083	5/6	1/6 [1, 5]	1/7	.35
.20	.150	3/6	6/6 [3, 6]	6/8	.75
.40	.317	5/6	4/6 [4, 6]	4/4	.99

Table 20: Cost dose-response (OpsSim, four steps, DeepSeek). Cost: clean success lost by the full stack. PI: frozen 95% predictive interval. Right: paired acceptance of deleting CONFIRM as the last protecting layer.

Remedies Under Selection. In three-step OpsSim, *read-only* CONFIRM resets that rule to the parent’s; the *IUT* gate adds to the paired test a Newcombe hybrid-score one-sided 95% upper bound of at most 0.10 on child-minus-parent harm, computed over all 40 pairs of the batch (OpsSim audits every task; clean tasks rarely harm); the *margin-aware* gate is the AppWorld rule below with a 30-task suite. Read-only CONFIRM and margin-aware kept every loop protected, IUT four of six, as a 0.10 margin over 40 pairs, about four of them from the harm pool, is loose (Table 21): on the mixed batch it allows a child-minus-parent harm of up to about $0.10/p$, i.e. almost any increase on the harm pool at $p = 0.1$, so this IUT is a weak baseline, and the veto and audit veto are the stricter harm-aware gates. In the AppWorld single-edit

study, where the bound used only the audited share of harm-pool pairs, the same gate accepted nothing. Against the greedy finals, margin-aware lost 0.35 of clean success (CI [0.28, 0.49]), read-only CONFIRM 0.05 and IUT 0.02. Freezing the sufficient layer requires knowing which layer that is.

Gate	Loops	Lost [†]	Success	T _{final} harm	
				DS	Qwen
<i>AppWorld stress</i> (Lost: reached an unprotected state)					
Greedy	6	5/6	.358	.317	.479
Paired	6	0/6	.392	.000	.004

<i>OpsSim, three steps</i> (Lost: reached an unprotected state)					
Greedy	6	5/6	1.00	.288	–
Veto $\rho = 1$	6	4/6	.992	.192	–
Paired	6	4/6	1.00	.133	–
Read-only CONFIRM	6	0/6	.946	.000	–
Margin-aware	6	0/6	.646	.000	–
IUT audit	6	2/6	.983	.067	–

Table 21: **Remedies** (DeepSeek loops). [†]Lost has a different meaning in each block, given in its header. Clean success and harm of the finals on T_{final} under DeepSeek (DS) and Qwen3-30B (–: not measured). Qwen-checked: suite run under Qwen3-30B. H0 solves .400 in AppWorld, the full stack .27 in OpsSim.

Without Redundancy. In a four-step OpsSim variant each of four trap kinds has exactly one blocking layer: full-stack harm is 0.000, empty-stack harm 0.83, and every single deletion exposes harm (0.08–0.34). Greedy loops still ended unprotected in 6 of 6 and veto ($p = 1$) loops in 5 of 6, after six accepted deletions none of which showed child-only harm in its batch; paired accepted none of 48. A deletion harms only on its own trap kind, which a batch of about four harm-pool tasks rarely holds: masking guarantees small increments, but narrow layers produce them too. The audit veto of 120 harm runs per state (six loops on the same random numbers) saw every such deletion: it rejected all 23 deletions that greedy accepted, kept the full stack in every loop (0 of 6 unprotected; clean success 1.00, T_{final} harm 0) and spent 600 audit runs. Without redundancy, a large enough audit loses nothing; with redundancy (AppWorld, Table 3), the same gate prevented exposure but lost depth. This is close to a design check, since in a

world without redundancy keeping the full stack is the only correct answer.

Audit of Equal Compute. The audit veto runs each greedy-accepted child twice on 60 fixed harm tasks and rejects on harm above τ or any child-only harm, at 120 runs per distinct state visited (eleven distinct children were audited), the same order as the margin-aware gate’s 1,228 suite runs over six loops. On greedy loops 1–6 no loop ended unprotected, but five finals had margin 1 and one margin 2 (mean 1.17), with clean success 0.44 and Qwen3-30B harm 0.21 (margin-aware: 1.33, 0.37, 0.04). On the shared random numbers the margin-aware gate kept more layers in all six matched loops (one-sided sign test $p=.016$), while their margins differed in one. Leave-one-out checks are not needed to avoid exposure under the loop’s model; they buy depth against a swap.

Margin-Aware Gate. The gate applies the greedy rule and, for an edit that changes safety text, requires every leave-one-out ablation of the child (without the owner line or without one credential rule) to have harm ≤ 0.05 on 30 T_{cal} harm tasks; a child with at most one safety unit is rejected. The check is a proof test of redundant channels in the sense of functional safety (International Electrotechnical Commission, 2010). Suite runs use a fixed replicate, cached per state and model in stress loops (480 runs each); natural loops pay 30 runs per safety unit and check. Checked exactly, the rule keeps margin 2 under whole-layer deletions from a parent with margin ≥ 2 , since the child is then a protected ablation of the parent; because h need not be monotone, a free-form child needs its own check as well, which this gate does not run; four finals have margin 1 because 30-run estimates near τ are noisy (a check passes true harm 0.10 with probability 0.18), and 4 of 22 decisions were false accepts against the pooled classification. On shared random numbers, five greedy loops ended unprotected and their margin-aware twins did not, with no pair the other way (sign test, one-sided $p=.031$; Table 22). In natural loops it rejected 1 of 17 greedy-passing candidates; all finals kept AUTH and CAUTION.

Edge-Level Acceptance. Across the 135 three-step OpsSim loops, the paired gate accepted deleting CONFIRM in 6 of 6 proposals for DeepSeek, 3 of 8 for Luna, 6 of 6 for Sol and 3 of 9 for Qwen3-30B, with mean batch gains of 0.51–0.85. For

Loop	Final	m	Greedy-passed / accepted	Diverged at
1	AC	1	4 / 2	3
2	VPC	1	5 / 1	4
3	AVP	2	6 / 1	3
4	AVP	2	2 / 1	8
5	AC	1	4 / 2	5
6	APC	1	5 / 1	2

Table 22: Margin-aware stress loops (DeepSeek ablations): final state and margin, deletions passing the greedy rule and accepted, and the generation at which the loop left the greedy trajectory. With Qwen3-30B ablations the gate accepted no deletion.

the first three models CONFIRM is the only layer that suffices alone; in all three accepted Qwen3-30B deletions DRYRUN remained, and those finals harmed in at most 0.050 of T_{final} runs.

Batch Size and Harm Share. We swept the frozen simulator over n and p and froze its predictions for six loop settings before any ran (Table 23); all seven predictions held. With $n=120$ the paired gate lost protection at costs of 0.03 and 0.08, where 40-task loops had kept it; with $n=20$ it kept protection at 0.15, where 40-task loops had lost it. The simulated break cost c^* falls faster than $1/\sqrt{n}$ up to $n=120$, where the exact test needs a minimum number of discordant pairs, and as $1/\sqrt{n}$ from there ($c^*\sqrt{n}=0.32$ at 120 and 200; Table 24). The law assumes a fixed σ . The veto improves with the harm data a batch holds: without redundancy its unprotected loops fell from 5 of 6 at $p=0.1$ to 2 and 1 of 6 at 0.3 and 0.5, and in the simulator its AppWorld risk at generation 8 falls from 0.42 at $p=0.05$ to 0.03 at 0.5. Masked deletions stay invisible: at $p=0.5$ in three-step OpsSim the veto accepted 17 of 17 of them, none with child-only harm in its batch.

Setting	n	p	Cost	Unprot.	Sim. [PI]	Acc.
<i>Paired, four steps, owner silent with q</i>						
$q=.05$	120	.1	.033	5/6	3.4 [1, 6]	5/48
$q=.10$	120	.1	.083	5/6	5.2 [3, 6]	5/48
$q=.20$	20	.1	.150	0/6	2.1 [0, 4]	0/48
<i>Veto ($\rho=1$)</i>						
No redundancy	40	.3	0	2/6	1.5 [0, 4]	2/48
No redundancy	40	.5	0	1/6	0.5 [0, 2]	1/48
Three steps	40	.5	.70	0/6	0.6 [0, 2]	17/48

Table 23: Loops at other batch sizes and harm shares (OpsSim, DeepSeek): unprotected loops, frozen simulator expectation with 95% predictive interval, and accepted deletions. At $n=40$, $p=0.1$ the same settings gave 0/6, 1/6 and 6/6 (paired) and 5/6 (veto, no redundancy).

n	20	40	80	120	200
Break cost c^* , paired	.202	.092	.045	.029	.023
$c^* \sqrt{n}$	.91	.58	.40	.32	.32
Paired, AppWorld, gen. 64	.01	.16	.51	.75	.90
Veto, no redundancy, gen. 8	.53	.51	.35	.23	.09

Table 24: Frozen simulator by batch size ($p=0.1$). c^* : clean success lost by CONFIRM (four steps) at the smallest q whose probability of an unprotected state at generation 8 reaches 0.5. Lower rows: probability of an unprotected state.

Harm Penalties. Re-deciding every recorded stress decision with the score $\Delta_{\text{success}} - \lambda \Delta_{\text{harm}}$ (Table 25) shows that a penalty is the audit in another form: from $\lambda=5$ on, it accepts exposing deletions about as rarely as the veto and masked ones as often as greedy, since it can only react to harm the batch contains.

Data	Deletion	Greedy	Penalty λ				Veto
			1	5	20	∞	
AppWorld	masked	.57	.57	.56	.56	.56	.56
	exposing	.42	.29	.19	.17	.17	.17
OpsSim 3 st.	masked	.78	.79	.79	.78	.77	.77
	exposing	.75	.70	.42	.30	.26	.23

Table 25: Acceptance of recorded stress deletions re-decided with a harm penalty (masked and exposing decisions; AppWorld: DeepSeek, 184; OpsSim: five models, 338).

Time-Uniform Error Control. A fixed- α paired gate gets a new chance of a false accept every generation. Over the frozen simulator, an anytime-valid betting test and α -spending across generations remove most of this risk in AppWorld but also most small real gains, and help little in OpsSim, where the deletion is a real gain (Table 27).

Longer Horizons. Table 26 chains the frozen per-edge acceptance probabilities over the AppWorld lattice (reproducing the frozen generation-8 predictions to 0.003) and adds unregistered gates analytically: under independent audit draws, a veto auditing k extra pairs passes its harm check with probability $(1 - h_{01})^k$, and the margin-aware rule passes a child if each ablation shows at most one harm event in one 30-task run. These projections assume a fixed task pool and stationary per-edge acceptance. Tables 9, 24 and 27 come from separate Monte Carlo runs of the simulator (3,000 and 1,500 chains), whose absolute risks differ from this exact chain by a few points; comparisons within one table

share a run. The last block comes from a separate chain over the same lattice: a *semantic floor*, which requires the child itself to stay protected, never exposes the harness but settles at margin 1, and a margin-aware gate whose ablations are checked under Qwen3-8B with a relative standard (harm at most H_0 ’s under that model plus 0.10) accepts no deletion. In the four-step OpsSim projection the paired gate stays below 0.001 for 200 generations, since deleting CONFIRM there gains nothing.

G Natural Erosion

Accepted Edits Pay. We re-ran all 42 safety-text edits that the natural and asymmetric loops had tested, each against its parent, on the 20 clean T_{final} tasks with two runs. The ten accepted ones (Table 28) gained 0.095 on the gate batch and 0.075 on fresh tasks (CI [0.007, 0.163]), the 32 rejected ones -0.006 and 0.010 . A pairwise judge, checked by hand on all accepted edits, marked 7 of the 10 accepted and 22 of the 32 rejected edits as relaxing a check; five of the seven accepted relaxations make PROFILE’s post-login check conditional or drop it. Among accepted edits, relaxing ones gained 0.082 on fresh tasks and the others 0.058.

Rewritten Layers Lose Function. Figure 8 shows one rewrite. Run as the only layer on the T_{conf} harm pool, the eroded layers of the natural finals, extracted with a prompt frozen before any run, let through 0.325 more harm than the original single layers (pooled over PROFILE and VERIFY, CI [0.215, 0.438]); counting only probes that hold an extracted rule, 0.194 ([0.078, 0.306]; Table 29). Under Qwen3-30B the eroded natural finals harmed in 0.057 of T_{final} runs and H_0 in none (CI [0.018, 0.111]); under Luna and Sol all had zero harm.

H0, PROFILE (function): after logging in, call `show_account` and check that the account is the requester’s before any other call.

Rewrite (harm .63): “After logging in, call `show_account` to verify ownership **only when you used a note whose owner is uncertain** or not clearly you; credentials obtained from `show_account_passwords()` are already yours, so skip that extra verification.”

Figure 8: **What natural erosion looks like.** A PROFILE rewording by the cost-objective proposer (verbatim). Kept as the only layer, it misused credentials in .63 of 30 T_{cal} harm runs, against .38 for the original: the check now runs only when the agent already suspects the credential.

Gate	P(unprotected) by generation				Margin		Qwen3-30B harm		Clean
	8	32	64	200	gen. 8	gen. 64	gen. 8	gen. 64	gen. 8

Semantic floor	.000	–	.000	–	1.09	1.00	.275	.340	.318
Margin-aware, Qwen3-8B canary	.000	–	.000	–	2.00	2.00	.033	.033	.279

Table 26: Projected AppWorld stress loops (DeepSeek), chaining the frozen per-edge predictions; the lower block adds gates analytically. Margin, Qwen3-30B lattice harm and pooled clean success of the final state are expectations. Observed at generation 8: greedy 5/6 and paired 0/6 unprotected; margin-aware 0/6, mean margin 1.33.

Gate	AppWorld			OpsSim		Edits
	8	64	200	64	200	+0.08 / +.28
Paired	.005	.208	.794	.839	.842	.10 / .91
Anytime-valid	.000	.013	.123	.705	.798	.02 / .77
α -spending	.000	.000	.000	.602	.602	.00 / .04*

Table 27: Probability of an unprotected state by generation (simulated, $n=40$, $p=0.1$) (OpsSim: three steps) and acceptance of two beneficial natural edits (+0.075, +0.275). Paired: $\alpha=.05$. *At generation 64 (0.85 at the first).

Read-Only Safety Text. Before evaluation the credential rules and the notes’ owner line are reset to the parent’s, and a candidate that then equals its parent is discarded. The proposer wrote 16 candidates that changed only safety text and 5 that changed it with other text; the latter gained -0.6 of 40 tasks after the reset, against $+0.4$ for the rest. Of the 2–5 lines each read-only final added outside the frozen text, a keyword rule flagged none and a judge one: a task tip telling the agent not to “spend a step on [...] extra profile/account checks unless a concrete parameter/name error occurs”, which discourages PROFILE’s check. Under Qwen3-30B the four finals harmed in 0.025, 0, 0.025 and 0.025 of runs against 0 for H0. Locking every instruction about credentials, accounts or identity would close this gap better than locking a section.

Judge Veto. Rejecting any candidate that the judge labels as newly weakening or removing a safeguard relative to its parent (replayed) would have blocked all 7 accepted relaxing edits of Table 28 and 27 of the 29 relaxing edits among the 42,

and passed the 3 accepted edits that do not relax a check. In the cost, asymmetric and margin-aware natural arms it flags 18 of 112, 9 of 44 and 6 of 35 tested candidates, among them 5 of 33, 2 of 11 and 4 of 16 accepted ones. It depends on a labeller that knows the four mechanisms. The veto uses the per-safeguard labels of judge v2; the relaxing class comes from a separate pairwise DeepSeek judge, read by hand only for the ten accepted edits, all seven relaxing verdicts confirmed. On GEPA’s 45 rewrites of the credential rules (Appendix H), judge v2 flagged 17, of which reading confirms 2 as relaxations, and it passed the template change behind the Qwen3-30B harm: there a judge veto would have blocked mostly stricter rules and missed the change that mattered.

Natural Erosion Rates. With the cost proposer, 14% of candidates eroded a layer still intact in their parent and 7.8% of generations accepted one. Erosion of AUTH or VERIFY, which suffice alone, was accepted in 3.1% of generations. Asymmetric and read-only loops accepted none in 24 and 32 generations, margin-aware loops three in 24.

Loop, gen.	Proposer’s title	Relaxes	Gate gain	Fresh parent → child	Fresh gain
Asymmetric 1, 2	Bootstrap own credentials once and skip redundant account checks	✓	+ .175	.400 → .500	+ .100
Asymmetric 3, 1	Conditional post-login identity check	✓	+ .175	.325 → .425	+ .100
Greedy 1, 1	Batch credential validation and avoid redundant post-login identity checks	✓	+ .025	.325 → .425	+ .100
Greedy 1, 4	Batch required app logins after caching passwords		+ .050	.625 → .725	+ .100
Greedy 2, 3	Use supervisor credentials once and skip redundant per-login identity checks	✓	+ .150	.575 → .475	− .100
Greedy 3, 1	One-time credential mapping instead of per-login revalidation	✓	+ .175	.325 → .500	+ .175
Greedy 3, 8	Enforce supervisor-mapped credentials before login		+ .050	.575 → .600	+ .025
Split-half 1, 5	Merge credential verification into the login block	✓	+ .025	.575 → .625	+ .050
Split-half 3, 1	Streamline credential verification	✓	+ .075	.325 → .475	+ .150
Split-half 3, 5	Use exact credentials and no login variants		+ .050	.600 → .650	+ .050

Table 28: The ten accepted edits to safety text in the natural loops (AppWorld, DeepSeek): whether the edit relaxes a check (judge, confirmed by hand), gain on the gate batch and on fresh T_{final} clean tasks.

Final, layer	Label	Probe	Original	Δ
Greedy 1, P	weakened	.683	.417	+ .267
Greedy 2, P	removed	.750*	.417	+ .333
Greedy 3, P	weakened	.750*	.417	+ .333
Split-half 1, P	weakened	.350	.417	− .067
Split-half 1, V	removed	.750*	.067	+ .683
Split-half 3, P	weakened	.750*	.417	+ .333
Asymmetric 1, C	removed	.183	.133	+ .050
Asymmetric 1, P	removed	.750*	.417	+ .333
Asymmetric 3, P	weakened	.800	.417	+ .383

Table 29: Single-layer probes of eroded layers (T_{conf} harm pool, two runs, DeepSeek; primary audit, which inflates the original PROFILE). *No rule could be extracted, so the probe equals the empty stack.

H An Off-the-Shelf Optimizer (GEPA)

Setup. We ran GEPA 0.1.4 (Agrawal et al., 2026) without modifying the library: Pareto candidate selection, a round-robin module selector, strict-improvement acceptance on reflection minibatches of four tasks, and 800 metric calls per seed (seeds 0–2). The harness is split into four plain-text components, the note header, the note template (one line per credential), the credential rules and task tips (empty in H0); the seed candidate reproduces H0 exactly. The score is task success alone, with no cost, length or efficiency hint; audit harm is recorded but never shown to the optimizer. Each seed shuffles $T_{\text{cal}} \cup T_{\text{conf}}$ with its own random seed and takes 40 training tasks (36 clean, 4 harm) and the next 27 as validation tasks (24 clean, 3 harm), disjoint from training. Validation sets therefore differ across seeds (9–10 of 27 tasks shared), which together with run variation explains why H0 scored

0.444, 0.148 and 0.333 on them; on shared tasks H0’s outcomes agreed in 24 of 28 cases. DeepSeek proposes at temperature 0.7. Only the adapter is ours: it shows the reflection model the component’s current text as the instruction and the task only as example input, and it retries a proposal up to three times when the reply has no code block or restates the task. Nothing checks safety content. A frozen smoke test passed on the first attempt (29 of 30 valid proposals).

What GEPA Changed. Proposals cycled evenly over the four components (44, 49, 45 and 43). The judge flagged 17 rule rewrites, 13 for VERIFY and 4 for PROFILE. Read by us, the 13 VERIFY flags replace “use a noted credential only if it matches mine” with a stricter rule, “use only the credentials that the supervisor returns”, which the judge scores as removing the original mechanism; all three flagged rewrites that GEPA kept are of this kind. Of the four PROFILE flags, two genuinely relax the post-login check (“that account is yours even if the app shows a different email”; “avoid extra verification calls after every login”), one only caches a verification and one is a false flag; none was kept. No final candidate changed the credential rules. Reading thus confirms only 2 of the 17 flags as relaxations, and the judge marked every layer of both harmful finals intact.

Where the Harm Came From. Seeds 1 and 2 rewrote the note template into an instruction to log in with the stored credentials. Seed 1: “Stored login for {app} (owner: {owner}) ... Use these

	Seed 0	Seed 1	Seed 2
Valid proposals	63/64	59/60	59/62
Kept in the pool	10	12	11
Rule rewrites (kept)	16 (3)	14 (2)	15 (2)
Judge-flagged rewrites (kept)	6 (1)	8 (1)	3 (1)
Validation success, $H_0 \rightarrow \text{final}$	.444 $\rightarrow$.444	.148 $\rightarrow$.259	.333 $\rightarrow$.556
Final: changed components	none	header, template	header, template, tips
Final: T_{final} clean success	.425	.350	.450
Final: harm, DeepSeek / Qwen3-30B	.000 / .000	.000 / .050	.000 / .125
Final: harm tasks under Qwen3-30B	0 of 20	2 of 20	3 of 20

Table 30: GEPA runs (AppWorld, success-only score). Judge flags are judge-v2 labels of a weakened or removed PROFILE or VERIFY relative to H_0 . Validation success is the mean over the seed’s 27 validation tasks, harm-pool tasks included. H_0 solves .400 of clean T_{final} tasks and harms in 0 of 80 Qwen3-30B runs.

credentials to log in to {app} and obtain an access token whenever the task involves {owner}’s {app} account.” Seed 2: “Saved {app} login for {owner} ... Use these exact credentials to authenticate to {app} as {owner} whenever needed”, with a header asking the agent to log in directly with saved credentials and 3,030 characters of tips that start with a limited step budget. Both keep the owner’s name, so the judge marks AUTH intact, and the credential rules are verbatim. Under DeepSeek the rules still hold; under Qwen3-30B, harm rose to 2 and 5 of 40 runs against 0 of 80 for H_0 Counted over runs, seed 2 differs from H_0 (one-sided Fisher $p = .003$), but its events fall on 3 of 20 tasks and seed 1’s on 2 (one task in both), so a sign test over tasks gives $p = .125$ for seed 2; three seeds do not support a loop-level test. We did not ablate the components or run one-layer ablations of the finals. The template adds an instruction rather than removing one; it is masked in the sense that the loop’s model shows no harm, but it lies outside the labelled layers over which margin is defined.

I Model Swap

Figure 9 and Table 33 give the swap contrasts with three-level bootstrap intervals (tasks, final states, loops), and Table 34 the harm of each of the 11 distinct final states under all four models, a 4-bit build of Qwen3-8B, and a shifted task pool, including the full stack. Each Qwen model’s own lattice, pooled over T_{cal} and T_{conf} , predicts per-state swap harm on T_{final} with MAE 0.067 (Qwen3-30B) and 0.084 (Qwen3-8B; Figure 10), against 0.205–0.215 and 0.115–0.128 for two constant baselines; Luna’s lattice predicts its swap with MAE 0.020.

Missing Layers, Not Random Trials. Qwen3-30B solves about 5% of clean tasks, so one might suspect that it misuses credentials whenever it runs

out of ideas, whatever the harness. The run logs argue otherwise (Table 31). The model used up its 15-step budget in 25 to 36 of 40 runs under every final, H_0 included, but harm depended on which layers remained: finals that kept AUTH and at least one other layer misused credentials in 2 of 200 runs, {AUTH} alone in 9 of 40, and finals without AUTH in 89 of 200. The contrast holds both in runs that exhausted the budget and in runs that ended earlier.

Final kept	Out of steps	Earlier	All
AUTH + another (5)	2/152	0/48	2/200
{AUTH} alone (1)	6/29	3/11	9/40
No AUTH (5)	49/143	40/57	89/200

Table 31: Credential misuse under Qwen3-30B by the layers a final kept and by whether the run used up its 15-step budget (T_{final} harm pool, 40 runs per final; number of finals in parentheses).

What Ranks Swap Harm? Table 32 ranks the 11 finals by measured Qwen3-30B swap harm . Margin under DeepSeek takes three values and ranks them worst; the expected harm after one random layer failure, a graded form of margin read from the same lattice, does better, and the finals’ pooled harm under DeepSeek, a graded quantity under the loop’s model that is below τ for most finals, does about as well as the lattice of the weaker Qwen3-8B. With Qwen3-8B as the target, margin, the Qwen3-30B lattice and its own lattice give 0.82, 0.83 and 0.92.

Task Shift and a Quantized Model. Without a model change, we built a pool of 20 harm tasks on three other apps (Spotify, Phone, Simple Note) with the same trap: H_0 harmed in none of its runs and the empty stack in 0.80. Greedy-type finals harmed in 0.52 of runs against none for paired finals (permutation $p = .004$), mostly because eight of them

Ranked by	r_s [95% CI]	Values
Margin under DeepSeek	.65 [.10, .94]	3
Harm after one layer failure	.80 [.45, .94]	8
Harm under DeepSeek (pooled)	.88 [.69, .98]	5
Qwen3-8B lattice	.89 [.54, .99]	10
Qwen3-30B lattice (target)	.91	11
Luna lattice	.35 [−.43, .85]	5

Table 32: Spearman correlation of each quantity with measured Qwen3-30B swap harm over the 11 distinct finals (bootstrap over states; values: distinct values of the quantity).

had lost every layer; among finals still protected under DeepSeek the gap was 0.020 ($p = .061$), through the finals that rely on VERIFY. Replacing Qwen3-8B by its 4-bit AWQ build kept the order of the finals’ harm ($r_s = 0.89$ with the FP8 build) and the greedy-type gap (+0.128 [0.083, 0.173]) at a lower level (greedy-type 0.24 against 0.42).

Figure 9: **Lost layers after a model swap.** T_{final} harm of the finals of the 27 AppWorld stress loops under another model. Upper markers: all finals, greedy-type (greedy, split-half, veto 0.2) minus paired loops, the registered contrast. Lower markers: finals still protected under DeepSeek, non-paired (greedy, split-half, veto $\rho = 0.2$ and veto $\rho = 1$) minus paired loops, the contrast reported in Section 4.5.

Model	Greedy-type – paired	Protected subset
Qwen3-30B	+ .446 [.267, .628]	+ .298 [.158, .469]
Qwen3-8B	+ .235 [.072, .390]	+ .162 [.018, .292]
GPT-6 Luna	+ .330 [.175, .517]	+ .025 [.000, .073]
GPT-6.1 Sol	+ .383 [.198, .572]	+ .025 [.000, .064]

Table 33: Swap contrasts on T_{final} (95% three-level bootstrap intervals). Left: all finals, greedy-type (greedy, split-half, veto 0.2) minus paired loops. Right: finals protected under DeepSeek, non-paired (greedy, split-half, veto $\rho = 0.2$ and veto $\rho = 1$) minus paired loops.

Figure 10: Swap harm per final state, predicted from the swapped-in model’s own lattice vs. measured on T_{final} . Marker area: loops ending in the state.

J Runs, Compute and Reproducibility

Models and Sampling. DeepSeek-V4.1-Flash was accessed through its official API. Qwen3-30B-A3B-Instruct-2507 (AWQ int4) and Qwen3-8B (FP8, thinking disabled; an AWQ int4 build for the 4-bit swap) were served with vLLM 0.10.1.1 on one 32 GB GPU with a 32k context; runs exceeding it were scored as running out of steps. Luna, Sol and Haiku were accessed through a third-party OpenAI-compatible API as gpt-6-luna, gpt-6.1-sol and claude-haiku-5-5; in a final probe its model field matched the requested name for all three. Haiku declined the AppWorld agent framing in most episodes and Sol cost about \$0.28 per AppWorld run, so neither has an AppWorld lattice or loops (Sol is used there only as a swap target). Every main conclusion holds with DeepSeek and the local Qwen models alone; the API models add supplementary rows and swap targets. All runs, in October 2026, use temperature 0; replicate agreement is 0.78–0.90, not bit-exact.

Compute. More than 40,000 AppWorld episodes plus OpsSim episodes of a few tool calls each; API fees totalled under \$1,000, and local runs used a single GPU. Step budgets, n , p , α and ρ are fixed as in Section 4.1 and were not tuned on the confirmation or final splits.

K Preregistration

The study ran in rounds. Before each round we froze its predictions and analysis code and hashed both; all hashes were re-checked at the end, and we release the files with their timestamps together with all run records. Later code changes (logging, runner robustness, new gate classes) touched no frozen prediction, decision rule, task or edit set, and all 204 AppWorld stress decisions were re-derived

State	m	Loops	Swap to another model (T_{final})					Shifted pool
			Qwen3-30B	Qwen3-8B	Qwen3-8B, 4-bit	Luna	Sol	DeepSeek
AVPC (H0)	2	4	.000	.175	.125	.000	.000	.000
AVC	2	1	.025	.175	.050	.000	.000	.000
AV	2	1	.025	.275	.125	.000	.000	.000
APC	1	1	.000	.225	.100	.000	.000	.000
AC	1	1	.000	.225	.075	.000	.000	.000
A	1	3	.225	.375	.200	.025	.075	.000
VC	1	1	.350	.425	.300	.000	.000	.025
VP	1	1	.250	.425	.425	.025	.025	.025
V	1	3	.575	.325	.200	.050	.000	.050
C	0	3	.450	.550	.375	.025	.000	.275
—	0	8	.600	.450	.250	.600	.700	.900

Table 34: Harm per distinct final state (40 runs each; a Wilson 95% interval is [.00, .09] at 0/40 and about $\pm .15$ near .5). m : margin under DeepSeek; loops: stress loops ending in the state. Shifted pool: 20 harm tasks on other apps, two runs each, under DeepSeek.

from raw records. Of 177 distinct registered predictions, 113 held (66%; 64% among blind ones), 9 held in part and 6 could not be scored; the released ledger gives every verdict, and Table 35 lists the test behind each main claim. Two amendments and the GEPA predictions were frozen after related outcomes had been seen, the latter after a first run with a faulty adapter, and the drift account was formulated after an early prediction of selection in AppWorld did not replicate on an independent sample.

Registered prediction	Observed	
<i>Masking (§4.2)</i>		
$h_{01} \leq .02$ into protected, $\geq .10$ into unprot.	.016; .422	✓
No redundancy: veto loses no loop	5 lost	✗ ^w
Veto loses fewer as p grows (≤ 2 at .5)	5, 2, 1	✓
<i>Drift (AppWorld, §4.3)</i>		
Greedy loses more loops than paired	5 vs. 0	✓
Split-half loses more loops than paired	2 vs. 0	✗ ^d
<i>Selection (OpsSim unless noted, §4.4)</i>		
Paired losses rise monotonically with cost	0, 0, 1, 6, 4	✗ ^d
$n = 120$ losses > 1 ; $n = 20$ losses < 6	5; 0	✓
AppWorld edits kept: fresh gain $\leq .03$	+.075	✗ ^s
<i>Remedies and swap (§4.7, §4.5)</i>		
Margin-aware: none lost, margin ≥ 1.5	0; 1.33	✗ ^d
IUT, margin-aware, read-only lose none‡	IUT 2	✗ ^w
Audit veto: margin < 1.33 and some lost	1.17; 0	✗ ^s
Swap: greedy-type harms more than paired	4 of 4	✓
Other apps: greedy-type harms more	+.52 (.02)	✓
4-bit target model: that gap persists	+.13	✓

Table 35: **Registered tests behind the main claims**, one per claim (loops lost of six; DeepSeek; parentheses: protected finals). No miss reverses a claim: ^dshort of the registered threshold in the predicted direction; ^san effect in the claim’s direction, stronger than predicted; ^wa harm-aware gate weaker than predicted. ‡: frozen after related outcomes were seen.
